

The try / except Structure

THE TRY / EXCEPT STRUCTURE

- You surround a dangerous section of code with try and except
- If the code in the try works - the except is skipped
- If the code in the try fails - it jumps to the except section

THE TRY / EXCEPT STRUCTURE

- What will happen if you run the following code?

```
astr = 'Hello Bob'  
istr = int(astr)  
print('First', istr)  
astr = '123'  
istr = int(astr)  
print('Second', istr)
```

THE TRY / EXCEPT STRUCTURE

- What will happen if you run the following code?

```
astr = 'Hello Bob'  
istr = int(astr)  
print('First', istr)  
astr = '123'  
istr = int(astr)  
print('Second', istr)
```

- You will run into an error message (red first two lines) and the rest of the code will not run.

THE TRY / EXCEPT STRUCTURE

```
astr = 'Hello Bob'  
try:  
    istr = int(astr)  
except:  
    istr = -1 ←  
  
print('First', istr)  
  
astr = '123'  
try:  
    istr = int(astr)  
except:  
    istr = -1  
  
print('Second', istr) ←
```

When the first conversion fails - it just drops into the except: clause and the program continues.

When the second conversion succeeds - it just skips the except: clause and the program continues.

BUILT IN ERROR

- just run:
`print(x)`
- You will receive error message

```
NameError                                 Traceback (most recent call last)
<ipython-input-2-81745ac23551> in <module>()
----> 1 print(x)

NameError: name 'x' is not defined
```

- Error type: NameError

SMOOTH CODING

this way, you run the
code smoothly

```
try:  
    print(x)  
except NameError:  
    print('x is not assigned')  
    error = -1  
if(error == -1):  
    x = 100  
    print(x)
```

ERROR TYPES

- You can find all of them here.
<https://docs.python.org/3/tutorial/errors.html>
- eg:
When writing robust code, say load some data.
You can use try/except to preprocess the data

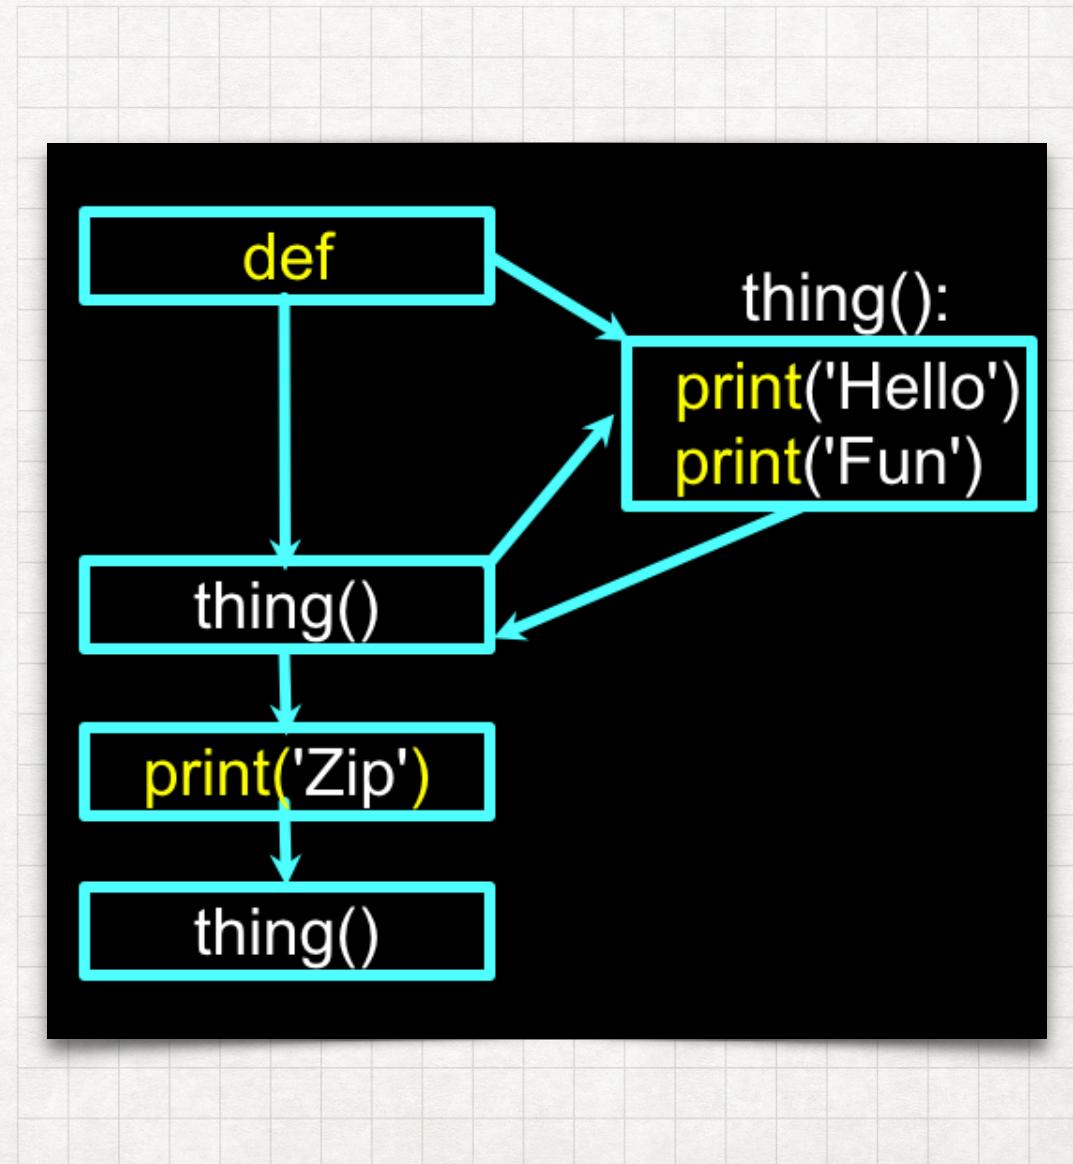

FUNCTIONS

STORED (AND REUSED) STEPS

- Program:

```
def thing():
    print('Hello')
    print('Fun')
```

```
thing()
print('Zip')
thing()
```

STORED (AND REUSED) STEPS

- function without input

Program:

```
def thing():
    print('Hello')
    print('Fun')
```

```
thing()
print('Zip')
thing()
```

Output:

Hello
Fun
Zip
Hello
Fun

PYTHON FUNCTIONS

- There are two kinds of functions in Python.
 - - Built-in functions that are provided as part of Python - `print()`, `input()`, `type()`, `float()`, `int()` ...
 - - Functions that we define ourselves and then use
- We treat the built-in function names as “new” reserved words (i.e., we avoid them as variable names)

FUNCTION DEFINITION

- In Python a function is some reusable code that takes arguments(s) as input, does some computation, and then returns a result or results
function: print
takes argument: (123)
returns: 123
- We define a function using the def reserved word:
thing()
- We call/invoke the function by using the function name, parentheses, and arguments in an expression

BUILT-IN FUNCTIONS

- You can find them here:

<https://docs.python.org/3/library/functions.html>

Built-in Functions				
<code>abs()</code>	<code>dict()</code>	<code>help()</code>	<code>min()</code>	<code>setattr()</code>
<code>all()</code>	<code>dir()</code>	<code>hex()</code>	<code>next()</code>	<code>slice()</code>
<code>any()</code>	<code>divmod()</code>	<code>id()</code>	<code>object()</code>	<code>sorted()</code>
<code>ascii()</code>	<code>enumerate()</code>	<code>input()</code>	<code>oct()</code>	<code>staticmethod()</code>
<code>bin()</code>	<code>eval()</code>	<code>int()</code>	<code>open()</code>	<code>str()</code>
<code>bool()</code>	<code>exec()</code>	<code>isinstance()</code>	<code>ord()</code>	<code>sum()</code>
<code>bytearray()</code>	<code>filter()</code>	<code>issubclass()</code>	<code>pow()</code>	<code>super()</code>
<code>bytes()</code>	<code>float()</code>	<code>iter()</code>	<code>print()</code>	<code>tuple()</code>
<code>callable()</code>	<code>format()</code>	<code>len()</code>	<code>property()</code>	<code>type()</code>
<code>chr()</code>	<code>frozenset()</code>	<code>list()</code>	<code>range()</code>	<code>vars()</code>
<code>classmethod()</code>	<code>getattr()</code>	<code>locals()</code>	<code>repr()</code>	<code>zip()</code>
<code>compile()</code>	<code>globals()</code>	<code>map()</code>	<code>reversed()</code>	<code>__import__()</code>
<code>complex()</code>	<code>hasattr()</code>	<code>max()</code>	<code>round()</code>	
<code>delattr()</code>	<code>hash()</code>	<code>memoryview()</code>	<code>set()</code>	

The diagram illustrates the components of the Python expression `big = max('Hello world')`. It features three colored arrows pointing to specific parts of the code:

- A green arrow labeled "Assignment" points to the assignment operator `=`.
- A magenta arrow labeled "Argument" points to the string argument `'Hello world'`.
- A yellow arrow labeled "Result" points to the variable name `w`, which is the result of the `max` function call.

big = max('Hello world')

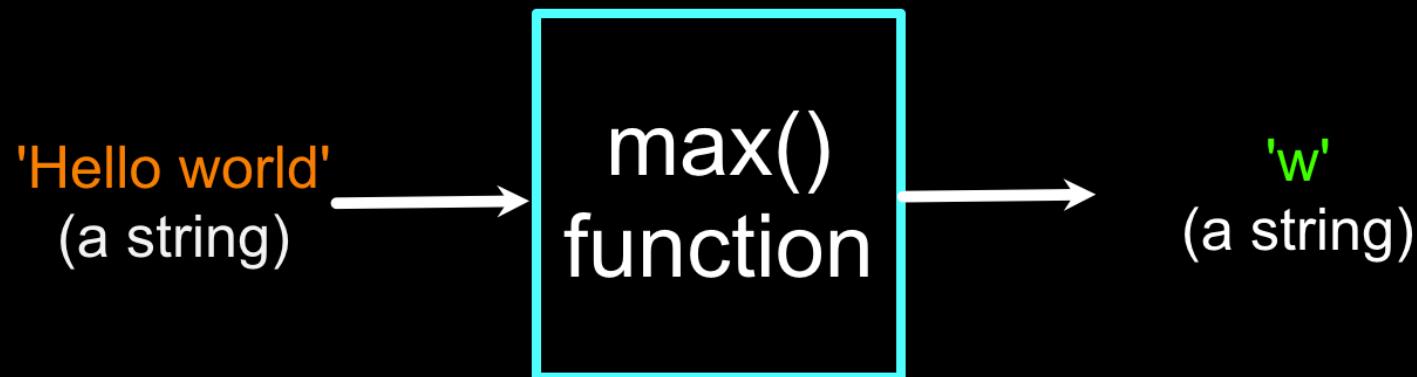

```
>>> big = max('Hello world')
>>> print(big)
w
>>> tiny = min('Hello world')
>>> print(tiny)
```

MAX FUNCTION

- A function is some stored code that we use. A function takes some input and produces an output.

```
>>> big = max('Hello world')
>>> print(big)
```

w

Guido wrote this code

TYPE CONVERSIONS

- When you put an integer and floating point in an expression, the integer is implicitly converted to a float
- You can control this with the built-in functions `int()` and `float()`
- Python3: no need for conversion
`print(2*3/4)`
1.5

```
>>> print(float(99) / 100)
0.99
>>> print(99 / 100)
0.99
>>> i = 42
>>> type(i)
<class 'int'>
>>> f = float(i)
>>> print(f)
42.0
>>> f = 1e2
>>> print(f)
100.0
```

STRING CONVERSIONS

- You can also use `int()` and `float()` to convert between strings and integers
- You will get an error if the string does not contain numeric characters

```
>>> sval = '123'
>>> type(sval)
<class 'str'>
>>> print(sval + 1)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: cannot concatenate 'str' and 'int'
>>> ival = int(sval)
>>> type(ival)
<class 'int'>
>>> print(ival + 1)
124
>>> nsv = 'hello bob'
>>> niv = int(nsv)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
ValueError: invalid literal for int()
```

STRING SUMMATION

- >>> sval1 = '123'

```
>>> type(sval)
```

```
<class 'str'>
```

```
>>> sval2 = '456'
```

```
>>> type(sval)
```

```
<class 'str'>
```

```
>>> ssum = sval1 + sval2
```

```
>>> type(ssum)
```

```
<class 'str'>
```

```
>>> print(ssum)
```

```
'123456'
```

RETURN VALUES

FUNCTION OF YOUR OWN

- Often a function will take its arguments, do some computation, and return a value to be used as the value of the function call in the calling expression. The return keyword is used for this.

```
def greet():
    return "Hello"
print(greet(), "Bob")
print(greet(), "Sarah")
```

Hello Bob
Hello Sarah

RETURN VALUE

FUNCTION OF YOUR OWN

- A “fruitful” function is one that produces a result (or return value)
- The return statement ends the function execution and “sends back” the result of the function

```
>>> def greet(lang):  
...     if lang == 'es':  
...         return 'Hola'  
...     elif lang == 'fr':  
...         return 'Bonjour'  
...     else:  
...         return 'Hello'  
...  
>>> print(greet('en'), 'Glenn')  
Hello Glenn  
>>> print(greet('es'), 'Sally')  
Hola Sally  
>>> print(greet('fr'), 'Michael')  
Bonjour Michael  
>>>
```

MULTIPLE PARAMETERS / ARGUMENTS

FUNCTION OF YOUR OWN

- We can define more than one parameter in the function definition
- We simply add more arguments when we call the function
- We match the number and order of arguments and parameters

```
def addtwo(a, b):  
    added = a + b  
    return added  
  
x = addtwo(3, 5)  
print(x)
```

LOOPS AND ITERATION
